(Received 20 June 2018; published 12 October 2018)

We generalize the temporally encoded spectral shifting (TESS) analysis for measuring plasma wakefields using spectral interferometry to dissimilar probe pulses of arbitrary spectral profile and to measuring nonlinear wakefields. We demonstrate that the Gaussian approximation used up until now results in a substantial miscalculation of the wakefield amplitude, by a factor of up to two. A method to accurately measure higher amplitude quasilinear and nonlinear wakefields is suggested, using an extension to the TESS procedure, and we place some limits on its accuracy in these regimes. These extensions and improvements to the analysis demonstrate its potential for rapid and accurate on-shot diagnosis of plasma wakefields, even at low plasma densities.

DOI: 10.1103/PhysRevAccelBeams.21.103501

I. INTRODUCTION

Acceleration of electrons by plasma wakefields has demonstrated much potential, with laser-driven plasma wakefield acceleration (LWFA) [1] producing electrons on the GeV scale over interaction lengths of just a few centimeters [2–4], while beam-driven wakefield acceleration (PWFA) [5,6] has used longer, metre scale plasma cells to boost electron energies by 10s of GeV [7,8]. In order to assist the development of this new technology, it is vital that sensitive, noninvasive diagnostics are developed which are capable of characterizing the wakefield structure and the electron beams they produced.

Measurement of the plasma wakefield is commonly made through changes in the refractive index of the plasma, determined by the effect on an optical probe through techniques such as shadowgraphy [9] and photon acceleration [10]. An optical probe passing through the plasma accumulates a phase change \( \delta \phi \propto n_e \int (\delta n_e/n_e) \, \text{d}x \) [11]. At high electron densities this phase change is large even when integrating over short interaction lengths; with electron densities of \( 10^{18} \) cm\(^{-3} \) and wake amplitudes of \( \delta n_e/n_e \sim 0.1 \), the phase accumulated is of the order of one radian after an interaction length of just 1 mm. However, as LWFA experiments aim to increase the energy gain, the length of the acceleration stages is increasing. To do this one must increase the dephasing length \( L_{\text{dp}} \propto n_e^{-1} \) by moving to lower plasma densities, around \( 10^{17} \) cm\(^{-3} \) [12,13]. Transverse probing techniques such as shadowgraphy, with an interaction length on the scale of the plasma wavelength \( \lambda_p \propto n_e^{-1} \), are no longer sufficiently sensitive, as the total phase change varies as \( \delta \phi \propto \lambda_p n_e \propto n_e^{-2} \).

Collective Thomson scattering is a useful diagnostic for measuring waves in these low density plasmas (e.g., [14]). However, when probing at an angle to the pump beam the geometry must be carefully matched to the very shallow scattering angle, which is dependent on the plasma density. Furthermore, the scattered power, which varies with the plasma wave amplitude as \( P_s \propto (\delta n_e/n_e)^2 n_e^2 \), is extremely small for weak plasma waves at low densities, requiring intense probe pulses or sensitive detectors. It is therefore more common in LWFA experiments to maximise the scattering rate by using a copropagating geometry, where the plasma wave is probed longitudinally (e.g., [15]). In this situation, it becomes difficult when using ultrashort broadband probe pulses to separate the scattered light from the original probe spectrum, leaving the Stokes and anti-Stokes spectral components poorly resolved and making it impossible in practice to extract information about the plasma wave. Using longer duration probe pulses would overcome this difficulty, but at the cost of reducing the temporal resolution.

Frequency domain interferometry (FDI) [16,17] and holography (FDH) [18] are some of the most sensitive techniques for longitudinally probing rapidly evolving density structures with high temporal resolution. In these methods, copropagating probe and reference pulses pass...
through an interaction region along the same path but are separated in time, such that the probe accumulates a phase change due to the density structure which the reference pulse does not. The interaction region is imaged onto the entrance slit of a spectrometer, giving spatial resolution of the density structure in one dimension, while in the spectrometer the separation between the probe and reference pulses leads to spectral interference, with a fringe spacing dependent on the delay between the pulses. The interference pattern contains information about the difference in phase shifts—and hence the local density of the plasma—experienced by the probe and reference pulses.

In both FDI and FDH the probe pulse copropagates with the plasma wakefield, and hence—assuming that these waves propagate at the same speed—these measurements can determine the electron density as a function of a local space coordinate fixed in the frame of the plasma wakefield. In FDI the probe pulse is shorter than the plasma wavelength, and hence scanning the delay between the probe and reference pulses allows the temporal behavior of the plasma wave to be mapped out. In FDH the probe and reference pulses are chirped and stretched, and hence the temporal dependence of the wakefield can be determined, in a single shot, from the spectral phase of the probe. However, the phase reconstruction analysis process in FDH requires several further measurements of the temporal and spectral phases of both the probe and reference pulses in order to distinguish the wakefield information from the intrinsic phase of the pulses. Recently, the technique of temporally encoded spectral shifting (TESS) [19] was developed to extract information about phase modulation, such as from plasma wakefields, without phase reconstruction. The method uses the same experimental set up as FDH but involves less computationally expensive analysis and requires fewer reference measurements.

To date, however, the TESS analysis has been restricted to the case of probe and reference pulses which have identical Gaussian spectral profiles. Here we extend the TESS method to the case of nonidentical probe and reference pulses of arbitrary spectral profile. We use experimental results to demonstrate that under real conditions the assumption of Gaussian probe and reference pulses can lead to significant errors in the deduced wakefield. We also extend the analysis to the case of nonlinear plasma wakefields and use simulations to show that the wakefield amplitude and frequency can accurately be recovered for quasilinear wakefields, and that the wakefield frequency can still be recovered for strongly nonlinear wakefields.

II. ARBITRARY PROBE AND REFERENCE PULSES

A. TESS in general

As described by Matlis et al. [19], a probe pulse copropagating with a linear plasma wave is transformed in a well-defined way. In the linear regime the plasma wakefield is sinusoidal, and information about the wakefield is encoded in the modulation of the spectrum of the probe by an additional phase \( \phi_{wake}(\xi) = \phi_1 \sin(\omega_0 \xi) \), where \( \omega_0 \rho_0 \) is the nonrelativistic plasma frequency, \( \xi = \tau - z/v_g \) is a comoving time coordinate for the probe pulse, which propagates at \( v_g \), and the amplitude of the phase is proportional to the density amplitude of the plasma wave, \( \phi_1 = \langle \omega_0^2 \rho_0 L / 2 \omega_0 c \rangle \delta n / n_0 \). This leads to the transformations between the electric field of the probe before entering the plasma, in temporal space \( E_{pr}^\prime(\omega) \) and in spectral space \( \mathcal{E}_{pr}(\omega) \), and after leaving the plasma, \( E_{pr}(\xi) \) and \( \mathcal{E}_{pr}(\omega) \), shown below:

\[
E_{pr}(\xi) = E_{pr}(\xi) e^{i \phi_1 \sin(\omega_0 \xi)} = E_{pr}(\xi) \sum_{k=-\infty}^{\infty} J_k(\phi_1) e^{ik\omega_0 \xi}. \tag{1}
\]

\[
\mathcal{E}_{pr}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} E_{pr}(\xi) e^{i \phi_{wake}(\xi)} e^{-i\omega \xi} d\xi = \sum_{k=-\infty}^{\infty} J_k(\phi_1) \mathcal{E}_{pr}(\omega - k\omega_0), \tag{2}
\]

where \( J_n(x) \) is the \( n \)th order Bessel function of the first kind.

From Eq. (2) we see that after it interacts with the plasma wave the spectrum of the transmitted probe pulse is a superposition of the original spectrum of the incident pulse and copies shifted in frequency by multiples of the plasma frequency, as shown in the cartoon in Fig. 1(a). The reference, meanwhile, remains unchanged, copropagating with the probe a time \( \Delta t \) earlier:

\[
E_t^r(\xi) = E_t(\xi + \Delta t). \tag{3}
\]

\[
\mathcal{E}_t^r(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} E_t^r(\xi + \Delta t)e^{-i\omega \xi} d\xi = \mathcal{E}_t(\omega) e^{t \omega \Delta t}. \tag{4}
\]

The two pulses interfere within the spectrometer to create a spectral interferogram \( S(\omega) = |\mathcal{E}_t^r(\omega) + \mathcal{E}_t(\omega)|^2 + \mathcal{E}_t^r(\omega)\mathcal{E}_t(\omega) + c.c. \), where c.c. denotes the complex conjugate of the previous term. In FDH the interferogram is analyzed as follows: First, one uses an inverse Fourier transform to the temporal domain to isolate the interference term, \( \mathcal{E}_t^r(\omega)\mathcal{E}_t(\omega) \), as described in Takeda et al. [20], before Fourier transforming back to the spectral domain. Next, one removes information about the reference pulse to recover the electric field of the transmitted probe, \( \mathcal{E}_t^r(\omega) \). From this, another inverse Fourier transform gives \( E_{pr}(\xi) \); removing the temporal phase of the probe and extracting the phase due to the wakefield one obtains \( \phi_{wake}(\xi) \).
In TESS, however, it is only necessary to make the first inverse Fourier transform to the temporal domain. This yields a TESS signal of the form shown schematically in Eq. 1(b). The form of the signal is given by [19]:

\[ s(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} S(\omega) e^{i\omega t} d\omega \]

\[ = H_{r,t}(t, 0) + \sum_{m=-\infty}^{\infty} g_m(\phi_1, t, \omega p_0) H_{pr,pr}(t, m\omega p_0) + \sum_{k=-\infty}^{\infty} J_k(\phi_1) [H_{pr,r}(t - \Delta t, k\omega p_0) + H_{pr,pr}(-t - \Delta t, k\omega p_0)] \]

(5)

where \( H_{a,b}(t, \Omega) \equiv \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} E_a(\omega - \Omega) E^*_b(\omega) e^{i\omega t} d\omega \)

(6)

and

\[ g_m(\phi_1, t, \Omega) \equiv \sum_{n=-\infty}^{\infty} J_n(\phi_1) J_{m+n}(\phi_1) e^{i\omega t} \]

(7)

which time the peak amplitude is described by a cross-correlation:

\[ |H_{pr,r}(t\Omega, \Omega)| = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |E_{pr}(\omega - \Omega)| |E_\Omega(\omega)| d\omega \]

(9)

From Eqs. (5) and (9) we see that in general the TESS signal is composed of the DC peak at \( t = 0 \), the two familiar delay sidebands at \( t_0 = \pm \Delta t \), and a series of equally spaced satellites either side of the delay sidebands, with the \( k \)th order satellite of the \( t_0 = \Delta t \) peak located at \( t_k = \Delta t + k\omega p_0 \psi^{(2)} \), see Eq. 1. This gives us a measurement of the wakefield frequency, using \( \omega p_0 = (t_k - \Delta t)/k\psi^{(2)} \), and hence an estimate of the electron density of the plasma, as

\[ n_e(t) = \omega p_0 m_e e^2 / \psi^{(2)}. \]

Additionally, the height of the satellite relative to that of the sideband is described by:

\[ \text{FIG. 1. (a) Frequency-time domain plots of the reference pulse, and the probe pulse after it has interacted with a sinusoidal plasma wave of frequency } \omega p_0. \text{ Modulation of the probe pulse generates copies of the incident probe pulse, spectrally shifted by multiples of } \omega p_0. \text{ (b) The TESS signal, obtained by a Fourier transform of the recorded spectrum of the transmitted probe and reference pulses. The temporal separation of the probe and reference pulses yields a DC term at } t = 0 \text{ and a sideband at } t = \Delta t, \text{ and modulation of the probe causes a series of satellites (lighter blue) separated from the sideband by multiples of } \omega p_0 \psi^{(2)}. \]
where the spectral overlap factor $F$ is given by:

$$F(\Omega) = \frac{\int_{-\infty}^{\infty} |E_{\text{pr}}(\omega - \Omega)||E_{\text{f}}(\omega)|d\omega}{\int_{-\infty}^{\infty} |E_{\text{pr}}(\omega)||E_{\text{f}}(\omega)|d\omega} = \frac{\int_{-\infty}^{\infty} \sqrt{I_{\text{pr}}(\omega - \Omega)} I_{\text{f}}(\omega)d\omega}{\int_{-\infty}^{\infty} \sqrt{I_{\text{pr}}(\omega)} I_{\text{f}}(\omega)d\omega},$$

(11)

where $I_{\text{pr}}$ and $I_{\text{f}}$ are the spectral intensities of the input probe and reference pulses. For probe and reference pulses of a bandwidth $\delta \omega$, we would expect this spectral overlap factor to become important when $\omega_{0}\delta \omega \gtrsim 1$.

For the case of identical Gaussian probe and reference pulses with $\sqrt{I(\omega)} = |E(\omega)| = Ae^{-\omega^2/(\delta \omega)^2}$ we find:

$$f(k\Omega) \equiv F_{\text{Gauss}}(k\Omega) = \exp \left[ -\left( \frac{k\Omega}{\delta \omega} \right)^2 \right],$$

(12)

which agrees with the result found by Matlis et al. [19].

Equation (12) can lead to inaccurate determination of the wakefield amplitude for practical probe and reference pulses. For example, in recent experiments [21] we measured low amplitude wakefields $\delta \omega / n_{\text{e}} \approx 1\%$ using frequency doubled probe and reference pulses, the spectra of which were far from Gaussian, as shown in Fig. 2(a). The spectrum has a bandwidth of approximately $\delta \omega \approx 40 \text{ rad ps}^{-1}$ and therefore a density of only $n_{\text{e}} \approx 0.5 \times 10^{18} \text{ cm}^{-3}$ produces a plasma frequency $\omega_{p0} \approx \delta \omega_0$. As a consequence, even at low electron densities the Gaussian approximation $F_{\text{Gauss}}(k\omega_{p0})$ used by Matlis et al. [19] diverges from the real overlap factor, making it unsuitable for accurately measuring wakefield amplitudes when the probe spectrum is non-Gaussian. For example, at a density of $n_{\text{e}} \approx 2.5 \times 10^{18} \text{ cm}^{-3}$, the Gaussian approximation reduced the calculated wakefield amplitude by a factor of approximately two.

Accurately measuring the wakefield frequency and amplitude over a range of experimental conditions can allow us to produce a resonance curve of wakefield amplitude with plasma frequency. In our recent experiments [21] we allowed us to infer information about the laser pulse which is driving the wakefield. For instance, for laser drivers with $a_0 \ll 1$ we expect the wakefield amplitude to increase linearly with the intensity of the drive pulse. Measuring violations of this trend would lead us to infer both an intense laser driver, with $a_0 \sim 1$, and a non-linear wakefield. We discuss estimating the wakefield amplitude under these conditions in Sec. III.

### C. Nonequal GDDs

In general, the probe and reference pulses will have different GDDs; this difference, which is usually small, arises from differences in the materials present in their optical paths. Whereas the previous work by Matlis et al. [19] has ignored these effects, they may cause changes in the locations of the satellites, and hence on the deduced plasma frequency. Using the Fourier shift theorem it can be shown that $H_{\text{pr},t}(t, k\omega_{p0}) = H_{\text{pr},t}(-t, -k\omega_{p0})e^{ik\omega_{p0}t}$ and the satellite peak location must depend equally on the probe and reference pulses. We show in the Appendix that for the case of non-identical Gaussian pulses the satellite peak is located at $t = \Delta t + k\omega_{p0}\psi_{\text{eff}}^{(2)}$, where $\psi_{\text{eff}}^{(2)}$ is the mean of the probe and reference GDDs, weighted by the square of their bandwidths:

$$\psi_{\text{eff}}^{(2)} = \frac{\delta \omega_{p0}^{2}\psi_{\text{pr}}^{(2)} + \delta \omega_{r}^{2}\psi_{\text{r}}^{(2)}}{\delta \omega_{p0}^{2} + \delta \omega_{r}^{2}}$$

(13)

In the case where probe and reference pulses have the same bandwidth $\delta \omega_{p0} \approx \delta \omega_{r}$, this reduces to the arithmetic
mean GDD $\psi''_{\text{eff}} = \frac{1}{2} [\psi''_{\text{pr}} + \psi''_{\text{tr}}]$. In previous experimental work [21] we measured a difference in GDDs of around 1000 fs$^2$ compared to $\psi''_{\text{eff}} \approx 20,000$ fs$^2$. In this case, using the probe GDD alone and assuming $\psi''_{\text{eff}} \approx \psi''_{\text{pr}}$ would result in an error in the calculated plasma frequency of around 2%.

## III. NONLINEAR WAKEFIELDS

### A. Quasilinear wakefields

We now consider the extension of TESS to the characterization of nonlinear plasma wakefields, where electrons in the plasma wave have relativistic velocities. Following Akhiezer and Noble [22,23], in the quasilinear regime the plasma wave amplitude can be described by the maximum electron velocity through $\beta_m = v_{\text{max}} / c$, where $\delta n_e / n_e = \beta / (1 - \beta)$ and $|\beta| \leq \beta_m$. The plasma waves are linear in the regime $\beta_m \ll 1$. Figure 3(a) shows the calculated relative wave amplitude $\delta n_e / n_e$ as a function of the comoving coordinate $\zeta$ for two values of $\beta_m$ at a plasma density of $n_e = 10^{18}$ cm$^{-3}$. It can be seen that as $\beta_m$ increases, the wave becomes more sharply peaked and the period of the plasma wave is increased as $\tau_p = \sqrt{\gamma} \tau_{p0}$, where $\gamma$ is the normal relativistic factor averaged over one cycle.

As the wakefield remains both periodic, with a period $\tau_p$, and continuous, the phase change acquired by the probe can be decomposed into a linear combination of harmonics: $\phi_{\text{wake}}(\zeta) \approx \sum_{n=1}^{N} \phi_n \sin(n\omega_0 \zeta + \theta_n)$, where $\omega_0 = \omega_{p0} / \sqrt{\gamma}$ and $N$ can be arbitrarily large. Figure 3(b) shows the amplitudes $\phi_n$ of the first five harmonics resulting from a 400 nm probe co-propagating over a distance of 1 mm with the plasma waves shown in Fig. 3(a). Whereas at $\beta_m = 0.3$ the phase change is dominated by the fundamental $n = 1$, as $\beta_m$ increases the wave becomes more nonlinear and the higher harmonics at $n > 1$ become relatively more significant. The Jacobi-Anger expansion can be applied to each of these $N$ harmonics as in the case of a linear wakefield, and so the electric field of the transmitted probe can be expanded as,

\[
 E'_{\text{pr}}(\zeta) = E_{\text{pr}}(\zeta) \prod_{n=1}^{N} e^{ik_n \sin(n\omega_0 \zeta + \theta_n)} 
 = E_{\text{pr}}(\zeta) \prod_{n=1}^{N} \left[ \sum_{k_n=-\infty}^{\infty} J_{k_n}(\phi_n) e^{ik_n(n\omega_0 \zeta + \theta_n)} \right] 
 = E_{\text{pr}}(\zeta) \sum_{k_1=-\infty}^{\infty} \cdots \sum_{k_N=-\infty}^{\infty} J_{k_1}(\phi_1) \cdots J_{k_N}(\phi_N) e^{i \left( \sum_{n=1}^{N} k_n \omega_0 \zeta + \sum_{n=1}^{N} k_n \theta_n \right)} 
\]

\[
 E'_{\text{pr}}(\omega) = \sum_{k_1=-\infty}^{\infty} \cdots \sum_{k_N=-\infty}^{\infty} J_{k_1}(\phi_1) \cdots J_{k_N}(\phi_N) e^{i \sum_{n=1}^{N} k_n \theta_n} E_{\text{pr}}\left( \omega - \sum_{n=1}^{N} k_n \omega_0 \right) 
\]

---

![Graphs and diagrams showing calculated temporal behavior, harmonic amplitudes, and TESS signals for different beta values.](image-url)
The transmitted probe spectrum therefore contains contributions from the $N$ (in principle, infinite) harmonics, each of which in turn produces an infinite set of carrier waves, labelled by the integers $k_n$, which can be both positive or negative. By truncating the phase expansion at finite $N$, each term is uniquely labeled with a set of indices, from $k_1$ to $k_N$. However, as $|k_n|$ increases, the amplitude of the carrier wave decreases since $|J_k\langle \phi_n \rangle| \to 0$ as $|k_n| \to \infty$. For any finite $\phi_n$ the carrier wave expansion can therefore be terminated at a finite value of $|k_n| \leq K$. The larger the phase $\phi_n$, the larger $K$ must be for accurate reconstruction of the wakefield. Every term in this expansion can therefore be described with a point on a discrete $N$-dimensional grid with $2K+1$ points on each side, although both $K$ and $N$ can be arbitrarily large; the point is described by $\mathbf{k} = (k_1, k_2, k_3, \ldots, k_N)$. There are $(2K+1)^N$ such points in the grid. The reference pulse is the same as before, and the interference between the two gives rise to a TESS signal. We shall consider only the term corresponding to the peaks near $t = \Delta t$, which arises from the interference term $\mathcal{E}^{\nu}\mathcal{E}^{\nu}(\nu)$, i.e.,

$$s(t) \approx \cdots + \sum_{k_1=-K}^{K} \cdots \sum_{k_N=-K}^{K} J_{k_1}\langle \phi_1 \rangle \cdots J_{k_N}\langle \phi_N \rangle e^{i \sum_{n=1}^{N} k_n \omega t} H_{pr,x}(t - \Delta t, \sum_{n=1}^{N} k_n n \omega p) + \cdots$$

$$= \cdots + \sum_{k=-K}^{K} \sum_{\kappa=K}^{N-K} Z_k(\{\phi_n\}, \{\theta_n\}) H_{pr,x}(t - \Delta t, \kappa \omega p) + \cdots$$

where $Z_k(\{\phi_n\}, \{\theta_n\}) = \sum_{k \in S_k} J_{k_1}\langle \phi_1 \rangle \cdots J_{k_N}\langle \phi_N \rangle e^{i \sum_{n=1}^{N} k_n \omega t}$.

For a subset $S_k = \{(k_1, \ldots, k_N) : \sum_{n=1}^{N} nk_n = \kappa\}$.

In Eq. (16) we have divided the set of points $\mathbf{k}$ in the grid into subsets, each labeled with the new integer $\kappa$, which, as seen in Eq. (16), is the effective harmonic order. Each of these subsets $S_k$ comprises those points from the original $N$ dimensional grid which also lie upon a particular $N-1$ dimensional plane, which is perpendicular to the vector $\mathbf{v} = (1, 2, 3, \ldots, N)$. The new label $\kappa$ is then the plane number, $\kappa = \mathbf{v} \cdot \mathbf{k}$, which can be both positive or negative. For instance, the $\kappa = 2$ subset contains points $\mathbf{k} = (2, 0, 0, 0, \ldots), (0, 1, 0, 0, \ldots), (-1, 0, 1, 0, \ldots)$, and $(2, -2, 0, 1, \ldots)$, amongst many others. To completely span the original grid we must consider all planes up to $|\kappa| \leq \kappa_{\text{max}} = K + 2K + \cdots + NK = KN(N+1)/2$.

The TESS signal $s(t)$ now looks very similar to that for a linear wakefield, with the substitution of a new complex number $Z_k$, which includes contributions from all of the wakefield’s frequency components, instead of the Bessel function $J_k$, which only accounts for the fundamental frequency. The crucial part of this signal again consists of a sideband peak at $t_0 = \Delta t$ and a series of satellite peaks spaced around it at times $t_r = \Delta t + n \omega_p$. For a quasilinear wakefield, however, each peak will contain contributions from many different frequency components; the $r$th order peak will have contributions from all terms in $S_k$, including all harmonics such that $\sum_{n=1}^{N} nk_n = \kappa$.

Figure 3(c) shows the TESS satellites resulting from the phase shifts shown in Fig. 3(b), for quasilinear plasma waves with $\beta_m = 0.3$ and $\beta_m = 0.6$. While the relative heights of the satellite peaks are slightly greater for $\beta_m = 0.6$, the form of the signal is largely unchanged from that of a linear wakefield. The satellites are located slightly closer to the origin because the plasma frequency is reduced as $\omega_p = \omega_{0p}/\sqrt{\beta}$. The satellite peak heights, relative to the sideband, are now:

$$r_\kappa = \left| \frac{Z_k(\{\phi_n\}, \{\theta_n\})}{Z_0(\{\phi_n\}, \{\theta_n\})} \right| \mathcal{F}(\kappa \omega_p).$$

In general, the wakefield is difficult to recover from measured $r_\kappa$, as every combination of $(k_1, k_2, \ldots, k_N) \in S_k$ must be accounted for. This set, the points of an $N$ dimensional grid of side length $2K+1$ which also lie on the $(N-1)$ dimensional plane $\kappa = \mathbf{v} \cdot \mathbf{k}$, contains on the order of $|S_k| \sim (2K+1)^{(N-1)}$ members and the contribution of each must be calculated. For example, limiting the set to $N = 5$, $K = 5$ gives $|S_2| = 2583$ solutions to $\kappa = 2$.

Once the sets $S_0$ and $S_2$ have been found for each of $N$ satellite peaks, obtaining the wakefield profile from the measured peak heights would involve measuring the amplitude and phase of $N$ satellite peaks, yielding $2N$ nonlinear simultaneous equations, and solving for the $2N$ unknowns $\{\phi_n\}$ and $\{\theta_n\}$. In practice, however, it is difficult to measure more than a few satellite peaks since the overlap factor $\mathcal{F}(\kappa \omega_p)$ becomes small as $\kappa$ increases.
Given a set of experimental parameters and a particular model of the wake, such as Akhiezer and Noble quasilinear plasma waves, it is nonetheless possible to tackle this problem numerically by calculating the values \{\phi_n\} and \{\theta_n\} for a range of wakefield amplitudes. Instead of 2\(N\) unknowns the wakefield is described by a single amplitude \(\beta_m\) and using \{\phi_n\} and \{\theta_n\}, a lookup table of ratios \(|Z_c/Z_0|\) against wakefield amplitudes \(\beta_m\) can be constructed. Comparing measured ratios to these values then yields the wakefield amplitudes. In the following section we demonstrate this approach for simulated data.

1. Simulated TESS analysis

In order to demonstrate this procedure, the TESS signals, similar to those shown in Fig. 3(c), were calculated for simulated plasma waves with maximum electron velocity \(\beta_m\) of up to 0.9, using the same probe frequency, plasma density and interaction length as above. From these TESS signals the peak ratios \(r_1\) and \(r_2\) were extracted and divided by the overlap factors to calculate \(|Z_1/Z_0|\) and \(|Z_2/Z_0|\). These simulated ratios were compared to expectations from Eq. (17), where \(Z_0\), \(Z_1\), and \(Z_2\) were calculated for cold 1D plasma waves as above. In all cases we limited the Bessel expansion to third order, \(|k_n| \leq 3\) as \(J_3(x)/J_1(x) < 0.13\) for \(x < 1\). We considered three possible analyses, with truncation of the harmonic expansion at: \(N = 1\), corresponding to assumption of a linear wakefield; \(N = 5\), for which there are around \(|S_{50}| \approx 400\) combinations; and \(N = 10\), for which \(|S_{50}| \approx 3\) million. The results, shown in Fig. 4(a), demonstrate that as wakefield amplitude increases more harmonics must be accounted for in Eq. (17) in order to correctly calculate the ratios \(|Z_1/Z_0|\) and \(|Z_2/Z_0|\). Whereas the linear approximation \(N = 1\) fails for \(\beta_m > 0.1\), using \(N = 10\) the simulations match the calculations very closely up to a wakefield amplitude of around \(\beta_m \approx 0.8\).

Next, these ratios were used to calculate lookup tables of \(|Z_1/Z_0|\) and \(|Z_2/Z_0|\) over different wakefield amplitudes; each value of \(N\) gave a different lookup table. The wakefield amplitude of the simulated TESS spectra was then estimated by using these lookup tables and the known interaction length and wakefield frequency. For each simulated TESS spectra we chose the value of \(\beta_m\) which minimized the distance (or 2-norm) between the measured ratios and the ratios on the lookup table. For \(N = 1\) we ignored \(Z_2\) and followed the same procedure as for linear plasma waves. As shown in Fig. 4(b), the linear assumption used in Sec. II works surprisingly well for nonlinear plasma waves, and the accuracy can be increased by further expanding \(N\). The linear TESS procedure, \(N = 1\), begins to diverge from the true value at wakefield amplitudes of \(\beta_m \approx 0.2\), or \(\delta n_e/n_{e0} \approx 25\%\), and subsequently overestimates the wakefield amplitude by around 10% of the true value. Using the \(N = 5\) expansion, however, accurately measures wakefield amplitudes up to \(\beta_m \approx 0.6\), and the expansion to \(N = 10\) only fails at \(\beta_m > 0.8\).

There is therefore a trade off between accuracy and computation time. We have demonstrated that an expansion to the 10th harmonic of the plasma frequency allows us to accurately calculate the amplitude of a quasilinear wakefield up to \(\beta_m \approx 0.8\). However, it requires calculating the sum of around 3 million components for each satellite peak at each wakefield amplitude, which takes several minutes on a desktop computer. When truncating the expansion to \(N = 5\) harmonics, however, the process requires only around 400 components and takes less than 0.1 seconds. These considerations are important as each lookup table is only valid for a certain experimental set up, with a given plasma density, probe frequency and interaction length. Once the lookup table is calculated, however, retrieval of the wakefield amplitude and frequency is extremely fast.
The analysis can be simplified in two cases. If the wake-field is not too nonlinear, \( \beta_m \ll 1 \), the original frequency component at \( \omega_p \) dominates, such that for \( \forall n > 1 \phi_n \ll \phi_1 \).

In this case, it is possible to truncate the expansion at \( N = 1 \) and use the same procedure as for linear wakefields, with \( r_1 \approx [J_1(\phi_1)/J_0(\phi_1)]F(\omega_p) \). This sacrifices only a small amount of accuracy, on the few percent level. On the other hand, if the phase change is sufficiently small, \( \phi(x) \ll 1 \), such as at low densities or short interaction lengths, it is feasible to limit the order of the Bessel peaks \( j_{kn} \leq 1 \), as \( J_2(x)/J_1(x) < 0.13 \) for \( x < 0.5 \). If we further allow only one \( k_n \) to be nonzero, the ratio of heights of the \( \kappa \)th satellite to the sideband is much easier to calculate:

\[
 r_\kappa = \frac{J_1(\phi_\kappa)}{J_0(\phi_\kappa)} F(\kappa \omega_p)
\]

This situation can always be achieved for a given experiment by reducing the interaction length until \( \phi(\zeta) \ll 1 \). As with conventional interferometry, phase changes which are too large make reconstruction difficult, but small phase changes are difficult to measure.

### B. General wakefields

In general, wakefields need not be periodic, and hence contain many frequencies which are not multiples of the plasma frequency. If we approximate this with a finite set of \( N \) frequencies, which are not uniformly spaced, the phase change due to the wakefield can be written \( \phi_w(\zeta) = \sum_{n=1}^{N} \phi_n \sin(\omega_n \zeta + \theta_n) \). By comparison with the results for a quasilinear wakefield with \( \omega_n \rightarrow \omega_n \) we can find the resulting TESS signal:

\[
 s(t) = \quad \sum_{k_1=-\infty}^{\infty} \cdots \sum_{k_N=-\infty}^{\infty} J_{k_1}(\phi_1) \cdots J_{k_N}(\phi_N) \\
 \cdot e^{i \sum_{n=1}^{N} k_n \theta_n \Omega_{p,n}} \left( t - \Delta t \sum_{n=1}^{N} k_n \omega_n \right) + \cdots \tag{21}
\]

While this looks very similar to the result for quasilinear wakefields, the peaks for general wakefields will lie either side of the original TESS satellites at locations \( t = \Delta t + \psi^{(2)}(\sum_{n=1}^{N} k_n \omega_n) \). These positions are not equally spaced and therefore each of the TESS satellites will be split into new peaks. However, as one of the sinusoidal components is at the plasma frequency, \( \omega_1 = \omega_p \), there will still be peaks at \( t_k = \Delta t + \psi^{(2)}(\omega_p) \), from the cases \( \{ k_n \} = \{ k, 0, 0, \ldots \} \).

This is demonstrated for example simulated wakefields, in (i) a weakly nonlinear regime and (ii) the bubble regime, shown in Fig. 5. In the bubble regime the ponderomotive...
force from an intense laser pulse is sufficient to completely evacuate a region of electrons, leaving only ions within a bubble with a diameter equal to the plasma period. The density maps were simulated with the EPOCH particle-in-cell code [24], with a bi-Gaussian drive laser with a peak beam intensity of (i) $2 \times 10^{18}$ W cm$^{-2}$ and (ii) $4 \times 10^{19}$ W cm$^{-2}$, passing through a high density plasma at $n_e = 10^{19}$ cm$^{-3}$. The pulse was matched to the plasma wavelength and period with a $\omega_p = 3 \mu$m spot and a duration of $t_{FWHM} = 13$ fs. The resulting density profiles are neither sinusoidal nor periodic and hence will contain many frequency components. The resulting TESS signals in both space and time were simulated for identical and Gaussian probe and reference pulses with 400 nm wavelength and 10 fs bandwidth limited duration, each stretched to 1 ps FWHM duration.

Figure 5(a) shows the density maps in the two cases: in the weakly nonlinear case several plasma periods are captured by the simulation, whereas in the bubble regime only two bubbles are shown, separated by $\tau_p$. Because the wakefield is strongly nonlinear the electrons are relativistic and the plasma period is longer than the duration, $\tau_p = \sqrt{\gamma} \tau_{p0}$, giving $\omega_p = \omega_{p0}/\sqrt{\gamma}$. Figure 5(b) shows the TESS signal for each spatial position of the simulation, with many peaks present at different spatial positions. The 1st and 2nd order satellites can be seen at locations $t_1 \approx \Delta t + 0.8 \omega_{p0} \Delta t^2$ and $t_2 \approx \Delta t + 1.6 \omega_{p0} \Delta t^2$, which implies that $\gamma \approx 1.6$. From this it is possible to estimate the wakefield amplitude as $\bar{\beta} \approx 0.8$, or $\delta n_e / n_{e0} \approx 4$, which is a substantial underestimate.

Recovering the wakefield amplitude more accurately is difficult as in general many frequencies are required to completely reconstruct the wakefield; the amplitude of the fundamental at a frequency $\omega_0$ is much smaller than the total height of the density fluctuation. Unlike periodic quasilinear wakefields, there is no way to know from the satellite peak heights alone whether the amplitude is reduced because of the shape of the wakefield or because there are only a few plasma periods present. With only two plasma periods present in the strongly nonlinear regime, applying the linear analysis of Sec. II to the TESS signal in Fig. 5(b) measures the density fluctuation as $\delta n_e / n_{e0} \approx 0.9$, which is a factor of 10 lower than the true value. In the weakly nonlinear regime, however, the wake amplitude is estimated as $\delta n_e / n_{e0} \approx 0.4$, close to the true value. In this situation the first TESS peak is sufficient for a first order approximation.

Figure 5(c) shows attempted reconstructions by instead measuring the location, amplitude and phase of all peaks up to $t = \Delta t + 3 \psi^{(2)} / \omega_{p0}$ at each spatial position of the TESS spectrum. The frequency of each component was deduced as $\omega_n = (t_n - \Delta t) / \psi^{(2)}$, where $t_n$ was the location of the $n$th peak; the amplitude was deduced from $r_n = |J_n(\phi_n)| / J_0(\phi_n)$, where $r_n = \Delta t / s(t_n)$ is the measured ratio of peak heights; and the phase was deduced from $\theta_n \approx \arctan[s(t_n) / \Delta t]$. This allowed us to reconstruct the phase change due to the wakefield as $\phi_{wake} \approx \sum_{n=1}^{N} \phi_n \sin(\omega_n \Delta t + \theta_n)$, for each spatial position, and hence to reconstruct the density map of the wakefield.

While some of the general features of the wakefield are reproduced, only a limited number of peaks ($N = 4$) were captured in the TESS signal and so this reconstruction inevitably fails to reproduce the true profile present in the simulation, particularly small spatial features. Whereas for the weakly nonlinear wakefield it is still possible to reconstruct the density with reasonable accuracy, for the simulation in the bubble regime the reconstruction fails and the calculated wakefield amplitude is more than an order of magnitude too small. The accuracy is limited by the number of peaks that can be captured in the TESS signal, which in turn is effectively limited by the bandwidth of the probe pulse and the overlap factor $\mathcal{F}(\omega_n)$. Sharp and nonperiodic features with durations less than the bandwidth limited duration of the probe pulse, for instance features such as an ionization front, are poorly reproduced by TESS, and are a source of noise when trying to extract the wakefield amplitude. Capturing shorter duration features requires using a shorter duration probe pulse with a broader bandwidth.

When attempting to reconstruct the density profile of a nonlinear wakefield with a continuous range of frequency components, FDH is therefore likely to be more effective than TESS. We can see this by considering another approach to this problem, where we can approximate the phase with $N$ uniformly spaced frequencies separated by an arbitrarily small frequency, $\delta \omega$. The phase can then be written as $\phi_{wake}(\xi) = \sum_{n=1}^{N} \phi_n \sin(n \delta \omega + \theta_n)$, where many of the amplitudes $\phi_n$ are small or zero. This is a discrete Fourier transform (DFT), and approximates the true phase profile increasingly well at larger $N$ and smaller $\delta \omega$. All of the information about the wakefield is contained in the region of the TESS signal surrounding the sideband at $t = \Delta t$, which can be written as:

$$s(t) = \ldots + \sum_{\kappa = -\infty}^{\infty} Z_{\kappa}(\{\phi_n\}, \{\theta_n\}) H_{\kappa}(t - \Delta t, \kappa \delta \omega) + \ldots,$$

where as before $\kappa = \sum_{n=1}^{N} k_n n$ and $Z$ is defined in Eq. (17). The potential TESS peaks are then separated by $\psi^{(2)} / \delta \omega$ although only some of these peaks will be nonzero. Fourier transforming this region of the TESS signal to the spectral domain yields:

$$S(\omega) = \ldots + \sum_{\kappa = -\infty}^{\infty} Z_{\kappa}(\{\phi_n\}, \{\theta_n\}) \cdot E_{\kappa}(\omega - \kappa \delta \omega) E_{\kappa}^{*}(\omega) e^{-i \omega \Delta t} + \ldots
= \ldots + E_{\kappa}(\omega) E_{\kappa}^{*}(\omega) + \ldots$$
The reference pulse in the spectral domain is unchanged, but the presence of the wakefield has modulated the electric field of the probe, creating many copies of the probe pulse, spectrally shifted by multiples of $\delta \omega$ and with amplitudes and phases described by $Z_n$. The frequency interval $\delta \omega$ can therefore be considered as the resolution of the DFT in the spectral domain. However, as the DFT becomes continuous with $\delta \omega \rightarrow 0$, these copies, and the resulting satellite peaks in the TESS signal, are no longer distinct. In the continuum limit we cannot measure relative peak heights and the TESS procedure will inevitable fail. Instead we have isolated the spectral component $E_{\nu m}^{\prime}(\omega)E_{\nu m}^{\prime\prime}(\omega)$ and must continue the FDH procedure to reconstruct the phase due to the wakefield.

1. Longitudinal variation

We have just discussed a situation where the wakefield is not periodic in the comoving frame. The same phase change can arise, however, if the background plasma density varies longitudinally and the plasma frequency changes along the path of the probe pulse. By the nature of the experimental set up both FDH and TESS average the density profile along this path, with each point $\zeta$ in the comoving frame corresponding to a line of points in space described by $z = v_o (t - \zeta)$. Whereas an FDH reconstruction risks obscuring the signal from one region by overlaying it with the signal from another region, TESS separates the density profile into its different frequency components. If the probe pulse encounters distinct regions of varying electron density along its path, such as in two stage injection-acceleration setups described in Refs. [25–27], the spectral interferogram will again contain components from several frequencies described by $\omega_n = \omega_p (z_n)$.

As described above, this will have the effect of creating new peaks in the TESS spectrum, where each corresponds to the plasma frequency at a particular region along the path of the probe pulse. However, if we are aware of the longitudinal variation of the plasma density and have measured the length of each region, we can again look only at uniformly spaced peaks from the sets \{$k_1, 0, 0, \ldots$, $\}$, \{0, $k_2, 0, 0, \ldots$, \}, \{0, 0, $k_3, 0, \ldots$, \} etc. These relate to distinct regions along the path of the probe pulse, each with a distinct plasma density. So long as these do not overlap, if the density ramps between different regions are sufficiently short, it is possible to reconstruct the wakefield frequency and amplitude within each region as before, using:

\[ t_{x,k} = \Delta t + k_x \psi (2) \omega_p x, \]

\[ r_{x,k} = \frac{J_{k_x}(\phi_x)}{J_0(\phi_x)} \mathcal{F}(k_x \omega_p 0), \]

and

\[ \phi_x = \frac{\omega_p x L_x}{2 \omega_0 c} \delta n_e, \]

where $L_x$ is the length of a region with plasma density $n_{e,x}$ and plasma frequency $\omega_{p,x}$. This causes a phase change of amplitude $\phi_x$ and peaks in the TESS spectrum at locations $t_{x,k_x}$.

IV. CONCLUSIONS

We have extended the TESS analysis technique to probe and reference pulses of arbitrary temporal and spectral profile. This allows more accurate measurement of the frequency and amplitude of the wakefield in real situations by using the measured spectra of the probe and reference pulses instead of a Gaussian approximation. In turn this allows us to calculate the electron density of the plasma and to infer information about the laser pulse driving the wakefield.

In calculating wakefield amplitudes using TESS, the generalized spectral overlap factor given in Eq. (11) can be calculated straightforwardly from the measured spectra of the probe and reference pulses. Using recent experimental results, we showed that the assumption of Gaussian probe and reference pulse spectra can lead to errors in the deduced amplitude of the plasma wakefield by a factor of around two. We have also demonstrated that when the probe and reference have different GDDs the TESS peak separation is described by the effective GDD, which is the mean of the probe and reference GDDs weighted by the square of their bandwidths.

We have also explored the applicability of TESS to measurements of nonlinear relativistic plasma waves by decomposing the wakefield into harmonics of the plasma frequency. Simulations showed that the extension of TESS to quasilinear plasma waves allowed accurate reconstruction of cold plasma waves with electron velocities as high as $\beta_m \approx 0.8$. For high wakefield amplitudes finding the peak height ratios involves solving a Diophantine equation and summing over millions of contributions, but at lower amplitudes or smaller phase shifts the wakefield amplitude can be extracted rapidly. TESS therefore retains its advantages over FDH for wakefields in the quasilinear regime. For general nonlinear wakefields, however, it was only possible to measure the wakefield frequency and not the amplitude, and in this regime an FDH phase reconstruction is required.

On the other hand, for wakefields in plasmas with distinct regions of different density TESS has the capability to extract the wakefield amplitude in each region separately, but only if the length of these regions are known.

The extension of TESS to quasilinear plasma waves is particularly relevant for measuring strong wakefields generated at low plasma densities. As laser wakefield experiments attempt to increase the electron energy gain through increasing the interaction length, TESS provides a means of rapidly diagnosing problems with the wakefield on-shot, without requiring electron injection. We have previously demonstrated [21] that TESS can work effectively at densities of $n_e \sim 10^{18}$ cm$^{-3}$ and below, accurately measuring wakefields with a relative amplitude as small as 1%. By demonstrating that TESS can also be effective for
plasma waves with density fluctuations on the scale of \( \delta n_e \sim n_e \), it is possible to envisage applying it to accurately measure large amplitude wakefields at electron densities below \( n_e \sim 10^{17} \text{ cm}^{-3} \).

APPENDIX: DETAILED TESS CALCULATIONS

We consider the probe and reference pulses to be nonidentical and to be of arbitrary spectral profile \( \mathcal{E}_p(\omega) = |\mathcal{E}_p(\omega)| \exp(i\psi_p) \). In evaluating Eq. (6) we will need to calculate the difference in spectral phase:

\[
\Delta \psi_{a,b}(\omega, \Omega) \equiv \psi_a(\omega, \Omega) - \psi_b(\omega) \\
= \left[ \psi_a^{(0)}(\omega, \Omega) + \frac{1}{2} \psi_a^{(2)}(\omega, \Omega)^2 + \cdots \right] \\
- \left[ \psi_b^{(0)}(\omega, \Omega) + \frac{1}{2} \psi_b^{(2)}(\omega, \Omega)^2 + \cdots \right] \\
= \frac{1}{2} \left( \psi_a^{(2)} - \psi_b^{(2)} \right)(\omega - \omega_0)^2 \\
+ \left( \psi_a^{(1)} - \psi_b^{(1)} \right)(\omega - \omega_0) \Omega + \left( \psi_a^{(0)} - \psi_b^{(0)} \right) \Omega + \frac{1}{2} \psi_a^{(2)}(\omega - \omega_0)^2 + \cdots \quad (A1)
\]

for \( A = \frac{1}{2}(\psi_a^{(2)} - \psi_b^{(2)}) \) \( (A2) \)

\[ B = \psi_a^{(1)} - \psi_b^{(1)} - \psi_a^{(2)} \Omega \quad (A3) \]

\[ C = \psi_a^{(0)} - \psi_b^{(0)} - \psi_a^{(1)} \Omega + \frac{1}{2} \psi_a^{(2)} \Omega^2 \quad (A4) \]

1. Case \( \psi_a^{(2)} = \psi_b^{(2)} \)

When the two pulses have equal GDD the coefficient \( A = 0 \) and hence:

\[
H_{a,b}(t, \Omega) \equiv \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \mathcal{E}_a(\omega, \Omega) \mathcal{E}_b(\omega) \exp(i\omega t) d\omega \\
= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |\mathcal{E}_a(\omega, \Omega)| \mathcal{E}_b(\omega) \exp[iB(\Omega)(\omega - \omega_0)] + iC(\Omega) + i\omega t d\omega \\
= \frac{1}{\sqrt{2\pi}} \mathcal{E}_a(\omega, \Omega) \mathcal{E}_b(\omega) \exp\{i\omega[B(\Omega) + t]\} d\omega \quad (A5)
\]

Since \( |\mathcal{E}_a(\omega, \Omega)| \mathcal{E}_b(\omega) \) is real, this integral is maximized when the phase \( p\omega = \omega[B(\Omega) + t] \) is stationary with respect to \( \omega \) at \( t_\Omega = -B(\Omega) = \psi_a^{(2)} \Omega + \psi_b^{(1)} - \psi_a^{(1)} \). At this peak, the integral has an amplitude:

\[
|H_{a,b}(t_\Omega, \Omega)| = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |\mathcal{E}_a(\omega, \Omega)| \mathcal{E}_b(\omega) |d\omega \quad (A6)
\]

2. Case \( \psi_a^{(2)} \approx \psi_b^{(2)} \)

The situation when the pulses have different GDDs is more complex, but progress can be made by treating \( H_{a,b}(t, \Omega) \) as a Fourier transform of a product, which is equal to the convolution of the individual Fourier transforms:
\[ H_{ab}(t, \Omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |\mathcal{E}_a(\omega - \Omega)||\mathcal{E}_b(\omega)| \exp \left[ i\psi_a(\omega - \Omega) - i\psi_b(\omega) + i\omega t \right] d\omega \]

\[ = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \left[ \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |\mathcal{E}_a(\omega' - \Omega)||\mathcal{E}_b(\omega')| e^{i\omega' t} d\omega' \right] \cdot \left\{ \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \exp \left[ i\Delta \psi_{ab}(\omega'', \Omega) + i\omega''(t - t') \right] d\omega'' \right\} dt' \]

\[ = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} K_{ab}(t', \Omega) \cdot L_{ab}(t - t', \Omega) dt' \quad (A7) \]

If we truncate the phase expansion in Eq. (A2) at second order, the phase term \( \Delta \psi_{ab}(\omega'', \Omega) + i\omega''(t - t') \) is a real quadratic and so the integral \( L_{ab}(t', \Omega) \) in Eq. (A7) is a Gaussian integral with a purely imaginary argument, or a Fresnel integral, which admits an analytic solution:

\[ L_{ab}(t - t', \Omega) = \frac{1}{\sqrt{2\pi}} \exp \left[ +iC(\Omega) + i\omega_0(t - t') \right] \cdot \int_{-\infty}^{\infty} \exp \left\{ -\frac{1}{4A} \left[B(\Omega)(t - t')^2 + iB(\Omega) + t - t' \right] \right\} d\omega'' \]

\[ = \frac{1}{\sqrt{2\pi}} \sqrt{\frac{\pi}{4A}} \exp \left\{ -\frac{1}{2} \left[ B(\Omega)(t - t')^2 + iB(\Omega) + t - t' \right] \right\} \]

\[ = \frac{1}{\sqrt{2\pi}} e^{iC(\Omega)} \exp \left[ i\omega_0(t - t') \right] e^{iB(t - t', \Omega)} \quad (A8) \]

where \( g(t, \Omega) = -\frac{1}{4}(B(\Omega) + t)^2 \) and \( \lambda = A^{-1} = 2(\psi_a^{(2)} - \psi_b^{(2)})^{-1} \). This means that for a given \( t \) and \( \Omega \) the integral \( H_{ab}(t, \Omega) \) is of the form \( \int f(x) e^{ig(x)} dx \) and if the difference between the probe and reference pulse GDDs is sufficiently small, \( \lambda \gg 1 \), \( g(t - t', \Omega) \) is an exact quadratic in \( t' \) and so if \( K_{ab}(t', \Omega) \) is sufficiently well behaved we can extend \( t' \) to the complex plane while ensuring that \( f(t', \Omega) \) and \( g(t - t', \Omega) \) are holomorphic. This allows us to deform the contour of integration \( \Gamma \) and use the method of steepest descent, with \( g(t - t', \Omega) \) having a single nondegenerate saddle point at \( t - t'_0 = -B(\Omega) \) at which point \( g(t - t'_0, \Omega) = 0 \) and \( g''(t - t'_0, \Omega) = -\frac{1}{B} \):

\[ H_{ab}(t, \Omega) = \frac{1}{\sqrt{2\pi}} \sqrt{\frac{i}{2A}} e^{iC(\Omega)} \int_{-\infty}^{\infty} K_{ab}(t', \Omega) e^{i\omega_0(t-t')} e^{iB(t-t', \Omega)} dt' \]

\[ \approx \sqrt{\frac{i}{4\pi A}} e^{iC(\Omega)} K_{ab}(t'_0, \Omega) e^{i\omega_0(t-t'_0)} \sqrt{\frac{2\pi}{\lambda}} e^{iB(t-t'_0, \Omega)} \left[ -g''(t - t'_0, \Omega) \right]^{-\frac{1}{2}} \]

\[ = \frac{1}{\sqrt{2\pi}} e^{iC(\Omega)} e^{-i\omega_0 B(\Omega)} \int_{-\infty}^{\infty} |\mathcal{E}_a(\omega' - \Omega)||\mathcal{E}_b(\omega')| e^{i\omega' t + B(\Omega) \omega'} d\omega' \quad (A9) \]

This expression is identical to Eq. (A5) for the case \( \psi_a^{(2)} = \psi_b^{(2)} \) and hence when the difference between GDDs is small but finite, the integral will again be maximized at approximately \( t_\Omega = -B(\Omega) = \psi_a^{(2)} - \psi_b^{(1)} = \psi_a^{(1)} \) with an amplitude given by Eq. (A6).

3. Case \( \psi_a^{(2)} \neq \psi_b^{(2)} \) for Gaussian \( |\mathcal{E}_x(\omega)| \)

The final tractable case is when pulses a and b can both be assumed to be Gaussian, but not identical, such that they can be described as:

\[ |\mathcal{E}_x(\omega)| = \mathcal{E}_{x0} \exp \left[ -\frac{1}{2} \left( \frac{\omega - \omega_0}{\delta\omega_x} \right)^2 - \sigma_x (\omega - \omega_0) \right], \quad (A10) \]

where \( \delta\omega_x \) is a measure of the spectral bandwidth of the pulse and \( \sigma_x \) allows the central frequency of the pulse to vary.
Then,

\[ |E_a(\omega - \Omega)||E_b(\omega)| = E_{a0}E_{b0}\exp\left[-\frac{1}{2}\left(\frac{\omega - \omega_0 - \Omega}{\delta\omega_a}\right)^2 - \sigma_a(\omega - \omega_0) - \frac{1}{2}\left(\frac{\omega - \omega_0}{\delta\omega_b}\right)^2 - \sigma_b(\omega - \omega_0)\right] \]

\[ = E_{a0}E_{b0}\exp\left[-\frac{1}{2}\left(\frac{1}{\delta\omega_a} + \frac{1}{\delta\omega_b}\right)(\omega - \omega_0)^2 - \left(\sigma_a + \sigma_b - \frac{\Omega}{\delta\omega_a}\right)(\omega - \omega_0) - \frac{\Omega^2}{2\delta\omega_a^2}\right] \]

\[ = E_{a0}E_{b0}\exp\left[-D(\omega - \omega_0)^2 - E(\Omega)(\omega - \omega_0) - F(\Omega)\right] \quad (A11) \]

This allows us to construct the integrand of \( H_{a,b}(t, \Omega) \) as a Gaussian, using \( \alpha \equiv D - iA, \beta(\Omega) \equiv E(\Omega) - iB(\Omega) \) and \( \gamma \equiv F(\Omega) - iC(\Omega) \), and hence to integrate it exactly, with the positive real part of \( \alpha \) ensuring convergence:

\[ H_{a,b}(t, \Omega) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} |E_a(\omega - \Omega)||E_b(\omega)| \exp[i\psi_a(\omega - \Omega) - i\psi_b(\omega) + i\alpha t]d\omega \]

\[ = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} E_{a0}E_{b0} \exp\{-\alpha(\omega - \omega_0)^2 - \beta(\Omega)(\omega - \omega_0) - \gamma(\Omega) + i\alpha t\}d\omega \]

\[ = \frac{1}{\sqrt{2\pi}} E_{a0}E_{b0} e^{-\gamma(\Omega)} e^{i\alpha t} \int_{-\infty}^{\infty} \exp\{-\alpha(\omega - \omega_0)^2 + |it - \beta(\Omega)|(\omega - \omega_0)\}d\omega \]

\[ = \frac{1}{\sqrt{2\pi}} E_{a0}E_{b0} e^{-\gamma(\Omega)} e^{i\alpha t} \sqrt{\frac{\pi}{\alpha}} \exp\left\{\frac{|it - \beta(\Omega)|^2}{4\alpha}\right\} \quad (A12) \]

\( H_{a,b}(t, \Omega) \) is a complex Gaussian and the real part of the argument of the exponential can be written:

\[ \Re\left\{\frac{|it - \beta(\Omega)|^2}{4\alpha}\right\} = \Re\left\{\frac{(D + iA)}{4(A^2 + D^2)} [it - E(\Omega) + iB(\Omega)]^2\right\} \]

\[ = \Re\left\{\frac{(D + iA)}{4(A^2 + D^2)} \left\{-[t + B(\Omega)]^2 + [E(\Omega)]^2 - 2iE(\Omega)[t + B(\Omega)]\right\}\right\} \]

\[ = \frac{1}{4(A^2 + D^2)} \left\{-D[t + B(\Omega)]^2 + D[E(\Omega)]^2 + 2AE(\Omega)[t + B(\Omega)]\right\} \]

\[ = \frac{1}{4(A^2 + D^2)} \left\{-D\left[t + B(\Omega) - \frac{AE(\Omega)}{D}\right]^2 + \frac{[AE(\Omega)]^2}{D} + D[E(\Omega)]^2\right\} \quad (A13) \]

Then the real part of \( H_{a,b}(t, \Omega) \) is therefore maximum at:

\[ t_\Omega = -B(\Omega) + \frac{AE(\Omega)}{D} \]

\[ = (\psi_a^{(2)} + \psi_b^{(1)}) + \frac{1}{2}(\psi_a^{(2)} - \psi_b^{(2)})\left(\sigma_a + \sigma_b - \frac{\Omega}{\delta\omega_a^2}\right) \left[\frac{1}{2}\left(\frac{1}{\delta\omega_a^2} + \frac{1}{\delta\omega_b^2}\right)\right]^{-1} \]

\[ = \left[\psi_a^{(1)} + (\psi_a^{(2)} - \psi_b^{(2)})\left(\sigma_a + \sigma_b - \frac{\Omega}{\delta\omega_a^2}\right) \left(\frac{\delta\omega_a^2\delta\omega_b^2}{\delta\omega_a^2 + \delta\omega_b^2}\right) + \Omega \left[\psi_a^{(2)} - (\psi_a^{(2)} - \psi_b^{(2)})\left(\frac{1}{\delta\omega_a^2} + \frac{1}{\delta\omega_b^2}\right)\right] \right] \]

\[ = t_0 + \Omega[(\delta\omega_a^2 + \delta\omega_b^2)\psi_a^{(2)} - \delta\omega_b^2(\psi_a^{(2)} - \psi_b^{(2)})] \left(\frac{1}{\delta\omega_a^2 + \delta\omega_b^2}\right) \]

\[ = t_0 + \Omega \frac{\delta\omega_a^2\psi_a^{(2)} + \delta\omega_b^2\psi_b^{(2)}}{\delta\omega_a^2 + \delta\omega_b^2} \quad (A14) \]

\[ = t_0 + \Omega \psi_{\text{eff}}^{(2)} \quad (A15) \]
This implies that instead of the GDD of pulse $a$, $\psi^{(2)}_a$, we should use the mean GDD of pulses $a$ and $b$, weighted by $t$.}

\[ t \approx \frac{1}{2} (\psi^{(2)}_a + \psi^{(2)}_b) \]

While the position of the main sideband $t_0$ is dependent on the central frequencies of the two pulses through $\sigma_a$ and $\sigma_b$, the separation of the peak from the main sideband, $\Omega \psi^{(2)}_{\text{eff}}$, is unaffected by changes in the central frequency of the two pulses.
