Made from stacks of two-dimensional materials, van der Waals heterostructures exhibit unique light-matter interactions and are promising for novel optoelectronic devices. The performance of such devices is governed by near-field coupling through, e.g., interlayer charge and/or energy transfer. New concepts and experimental methodologies are needed to properly describe two-dimensional heterointerfaces. Here, we report an original study of interlayer charge and energy transfer in atomically thin metal-semiconductor [i.e., graphene-transition metal dichalcogenide (TMD, here molybdenum diselenide, MoSe₂)] heterostructures using a combination of microphotoluminescence and Raman scattering spectroscopies. The photoluminescence intensity in graphene/MoSe₂ is quenched by more than 2 orders of magnitude and rises linearly with the incident photon flux, demonstrating a drastically shortened (about 1 ps) room-temperature MoSe₂ exciton lifetime. Key complementary insights are provided from a comprehensive analysis of the graphene and MoSe₂ Raman modes, which reveals net photoinduced electron transfer from MoSe₂ to graphene and hole accumulation in MoSe₂. Remarkably, the steady-state Fermi energy of graphene saturates at 290 ± 15 meV above the Dirac point. This reproducible behavior is observed both in ambient air and in vacuum and is discussed in terms of intrinsic factors (i.e., band offsets) and environmental effects. In this saturation regime, balanced photoinduced flows of electrons and holes may transfer to graphene, a mechanism that effectively leads to energy transfer. Using a broad range of incident photon fluxes and diverse environmental conditions, we find that the presence of net photoinduced charge transfer has no measurable impact on the near-unity photoluminescence quenching efficiency in graphene/MoSe₂. This absence of correlation strongly suggests that energy transfer to graphene (either in the form of electron exchange or dipole-dipole interaction) is the dominant interlayer coupling mechanism between atomically thin TMDs and graphene.

I. INTRODUCTION

Charge and energy transfer (CT, ET) play a prominent role in atomic, molecular, and nanoscale systems. On the one hand, Förster-type energy transfer [1], mediated by relatively long-range (up to several nm) near-field dipole-dipole coupling, is an essential step in photosynthesis [2] and is now engineered in a variety of light-harvesting devices and distance sensors [3,4]. Charge transfer, on the other hand, is a much shorter-range process (about 1 nm) that plays a key role in a number of molecular and solid-state systems and is at the origin of the operation of photodetectors and solar cells [5,6]. In the limit of orbital overlap between donor and acceptor systems, electron exchange, resulting in no net charge transfer and also known as Dexter-type energy transfer [7], may occur. The efficiencies of CT and ET depend very sensitively on the donor-acceptor distance, on the energy-level (or bands) offsets, and on the local dielectric and electrostatic environment. CT and ET processes may have beneficial or detrimental impact on the performance of optoelectronic devices and therefore deserve fundamental investigations.

In this context, two-dimensional materials [2D—such as graphene (Gr), boron nitride, transition metal dichalcogenides (TMDs), black phosphorus,…] provide an extraordinary toolkit to investigate novel regimes of CT and ET. Indeed, the very diverse and complementary physical properties of 2D can be tailored and controlled at the single-layer level but also combined and possibly enhanced within so-called van der Waals heterostructures (vdWHs) [8–10]. The vdWHs provide a new paradigm of...
clean, ultra-smooth, two-dimensional heterointerfaces [11]. Since their van der Waals gap is only of a few Å, band bending and depletion regions cannot develop in vdWH. As a result, well-established concepts borrowed from the physics of bulk or low-dimensional heterojunctions [6] must be adapted with great care when describing the optoelectronic response of vdWHs. In addition, the ultimate proximity between the atomically thin building blocks that compose a vdWH potentially allows ultra-efficient CT and/or ET.

Among the vast library of 2DM, graphene [12] and atomically thin semiconducting TMDs (with formula MX₂, with M = Mo, W and X = S, Se, Te) [10,13,14] have attracted particular interest for optoelectronic applications [15–25]. Indeed, graphene may act as a highly tunable transparent electrode, endowed with exceptional physical properties [26–28], while monolayer TMDs are direct band-gap semiconductors with unusually strong light-matter interactions and excitonic effects [10,29,30], as well as unique spin, valley, and optoelectronic properties [10,30,31]. Photodetectors based on graphene and TMDs display high photoresponsivity and photogain [15–19], down to picosecond time scales [20]. The photophysics of Gr/TMD vdWHs is governed by near-field interlayer CT and/or ET (ICT, IET). In the related and most-studied case of TMD/TMD heterojunctions with type-II band alignment, subpicosecond ICT and subsequent interlayer exciton formation is thought to be the dominant coupling mechanism [31–36]. However, recent photoluminescence excitation spectroscopy studies in MoSe₂/WS₂ vdWH have suggested that IET may be at least as efficient as ICT [37].

In contrast, fundamental studies of IET and ICT remain scarce in Gr/TMD vdWH. Photoinduced ICT has been observed in Gr/MoS₂ photodetectors [18]. Recent transient absorption studies have evidenced fast interlayer coupling in Gr/WS₂ vdWHs and tentatively assigned it to photoinduced ICT [24]. Yet, such studies were mostly performed under ambient conditions, and the environmental effects need to be assessed. Importantly, in Ref. [20], the internal quantum efficiency of Gr/TMD photodetectors degrades when the active TMD layer is thinned down to the monolayer limit, possibly due to efficient IET to graphene. Overall, IET has been surprisingly overlooked in vdWH, whereas related studies in hybrid heterostructures composed of nanoscale emitters (molecules, quantum dots, quantum wells,...) interfaced with carbon nanotubes [38], graphene [39–42], and TMDs [43,44] have consistently demonstrated highly efficient Förster-type ET.

Unraveling the relative efficiencies of ICT and IET in vdWH is a timely challenge for optoelectronics. For this purpose, optical spectroscopy offers minimally invasive and spatially resolved tools. First exciton dynamics and interlayer coupling can be probed with great sensitivity using microphotoluminescence (PL) spectroscopy [10,31]. Second, micro-Raman scattering spectroscopy allows quantitative measurements of doping and CT, as it has been demonstrated in graphene [45–49] and in MoS₂ [50,51] but not yet in vdWHs.

In this paper, using an original combination of PL and Raman spectroscopies, we are able to disentangle contributions from ICT and IET in model vdWHs made of single-layer graphene stacked onto single-layer molybdenum diselenide (MoSe₂) (hereafter denoted Gr/MoSe₂) in the absence of any externally applied electric field. While highly efficient exciton-exciton annihilation and subsequent saturation of the PL intensity is, as expected, observed in bare MoSe₂ as the incident photon flux is increased, the PL in Gr/MoSe₂ is massively quenched, and its intensity rises linearly with the incident photon flux, demonstrating a drastically shortened room-temperature exciton lifetime in MoSe₂. Key complementary insights are provided from a comprehensive analysis of the graphene and MoSe₂ Raman modes, which reveals net photoinduced electron transfer from MoSe₂ to graphene and hole accumulation in MoSe₂. Remarkably, the steady-state Fermi energy of graphene saturates at 290 ± 15 meV above the Dirac point. In this saturation regime, balanced flows of electrons and holes transfer to graphene, resulting in no net photoinduced charge transfer. This reproducible behavior is observed both in ambient air and in vacuum and is discussed in terms of intrinsic factors (i.e., band offsets) and extrinsic effects associated with native doping and charge trapping. Using a broad range of incident photon fluxes and diverse environmental conditions, we find that the existence of net photoinduced charge transfer has no measurable impact on the near-unity photoluminescence quenching efficiency in graphene/MoSe₂. This absence of correlation strongly suggests that energy transfer to graphene (either in the form of Dexter or Förster processes) is the dominant interlayer coupling mechanism between atomically thin TMDs and graphene. Our results provide a better understanding of the atomically thin, two-dimensional, metal-semiconductor (i.e., Schottky) junction, a ubiquitous building block in emerging optoelectronic devices, and will serve as a guide to engineer charge-carrier and exciton transport in two-dimensional materials.

II. CHARACTERIZATION OF THE Gr/MoSe₂ HETEROSTRUCTURE

Figure 1(a) shows an optical image of a Gr/MoSe₂ vdWH (sample S₁) deposited onto a Si/SiO₂ substrate (see Appendix for details on sample fabrication). From AFM measurements (see Ref. [52], Fig. S1), we can distinguish a region of the heterostructure [highlighted with a white dashed contour in Fig. 1(a)], where the two layers are well coupled, as evidenced by the small surface roughness [9] and the small height difference of approximately 0.65 nm between the surface of MoSe₂ and Gr [see Fig. 1(b)]. Outside this region, the interface shows submicrometer size “pockets” and an average step of about 2–3 nm [see Fig. 1(b)] between MoSe₂ and Gr. Hereafter, these two regions are
referred to as coupled and decoupled Gr/MoSe$_2$, respectively [see Fig. 1(c) and Ref. [52], Fig. S1].

Typical photoluminescence (PL) and Raman spectra from three different points of the sample are shown in Figs. 1(d) and 1(e), respectively. Unless otherwise noted, the samples were optically excited in the continuous-wave regime using a single longitudinal-mode, linearly polarized laser at a photon energy of 2.33 eV, well above the optical band gap of MoSe$_2$.

Figures 1(f)–1(k) display the hyperspectral maps of (f) the MoSe$_2$ PL intensity, (g)–(j) the frequencies ($\omega_{G,2D}$) and full widths at half maximum (FWHM, $\Gamma_{G,2D}$) of the Raman G- and 2D-mode features [53], and (k) the ratio of their integrated intensities ($I_{2D}/I_G$). Note that no defect-induced D-mode feature [53] (expected around 1350 cm$^{-1}$) emerges from the background [see Fig. 1(e)], showing the very good quality of our sample. All hyperspectral maps allow us to distinctively identify the coupled and decoupled Gr/MoSe$_2$ regions and confirm the trends observed on selected points.

The PL spectra in Fig. 1(d) are characteristic of single-layer MoSe$_2$, with the $A$ and $B$ excitons [54] near 1.57 eV and 1.75 eV, respectively. Remarkably, the MoSe$_2$ PL intensity is about 300 times smaller on coupled Gr/MoSe$_2$ than on MoSe$_2$/SiO$_2$, while it is only reduced by a modest factor of approximately 2 on decoupled Gr/MoSe$_2$ [Figs. 1(d) and 1(f)]. Such massive PL quenching, also observed for other Gr/TMD vdWHs [20,24], demonstrates strong interlayer coupling and suggests a much-reduced exciton lifetime.
As shown in Figs. 1(e) and 1(g)–1(k), interlayer coupling also dramatically affects the Raman response of graphene. Indeed, on coupled Gr/MoSe$_2$, the $G$-mode feature upshifts and becomes narrower, and the $I_{2D}/I_G$ ratio decreases [Fig. 1(k)] with respect to reference measurements on the neighboring pristine graphene deposited on SiO$_2$ (Gr/SiO$_2$) and decoupled Gr/MoSe$_2$ regions [Figs. 1(e) and 1(k)]. These observations are robust evidence of an increased charge carrier concentration in graphene [47,48]. Surprisingly, we observe an upshift of the 2D-mode frequency on coupled Gr/MoSe$_2$ [Fig. 1(i)], which is too high to be solely induced by doping or strain [48,55,56] and seems qualitatively similar to previous reports on graphene deposited on thick boron nitride terraces [57,58] and monolayer MoS$_2$ grown on graphene [21]. Possible origins for this upshift are discussed in Ref. [52] (Fig. S15).

In the following sections, we quantitatively investigate exciton dynamics (Sec. III) and interlayer charge transfer (Sec. IV).

III. EXCITON DYNAMICS IN Gr/MoSe$_2$

Although PL quenching has been reported in previous studies of Gr/TMD heterostructures (see Fig. 1 in Ref. [59] and Supplementary Fig. 6 in Ref. [20]), quantitative analysis of PL quenching and its interpretation in terms of IET and ICT have not been reported thus far. Figures 2(a) and 2(b) display the normalized PL spectra of MoSe$_2$ recorded on MoSe$_2$/SiO$_2$, and decoupled and

![Normalized photoluminescence spectra of MoSe$_2$ recorded in the cw regime at a laser photon energy of 2.33 eV, with an incident photon flux (a) $\Phi_{ph} = 3 \times 10^{20}$ cm$^{-2}$ s$^{-1}$ and (b) $\Phi_{ph} = 5 \times 10^{23}$ cm$^{-2}$ s$^{-1}$ for MoSe$_2$/SiO$_2$, and decoupled (D) and coupled (C) Gr/MoSe$_2$. The $A$ and $B$ excitons are labeled, and the position of the $A$ exciton in MoSe$_2$/SiO$_2$ is indicated by a gray vertical dashed line. (b) Integrated photoluminescence intensity of the (c) $A$ and (d) $B$ exciton normalized by $\Phi_{ph}$ as a function of $\Phi_{ph}$. The gray dashed line is a guide to the eye. The error bars are smaller than the symbol size. (e) Photoluminescence decays recorded using a pulsed laser at 1.96 eV with a fluence of $2.2 \times 10^{11}$ cm$^{-2}$ per pulse. The gray area corresponds to the instrument response function (IRF). All measurements were performed in ambient air.](image-url)
coupled Gr/MoSe₂ at low- and high-incident photon flux $\Phi_{\text{ph}}$. The A exciton PL feature of coupled Gr/MoSe₂/SiO₂ is marginally redshifted (by $\approx 10 \text{ meV}$) with respect to that of air/MoSe₂/SiO₂, irrespective of $\Phi_{\text{ph}}$. Considering the drastically different dielectric environments, such a surprisingly small reduction of the optical band gap is assigned to the near-perfect compensation of the reductions of the electronic band gap and exciton binding energy in graphene-capped MoSe₂ [60–62]. The line shapes of the A-exciton features are quite similar, except for a small but reproducible narrowing of the A-exciton linewidth in coupled Gr/MoSe₂. Similar narrowing has recently been observed in TMD layers fully encapsulated in boron nitride [63,64] and likely results from a reduction of inhomogeneous broadening and pure dephasing in graphene-capped TMD samples.

The integrated PL intensities of the A and B-exciton features (denoted $I_{\text{PL}}^{A,B}$) normalized by $\Phi_{\text{ph}}$ are plotted as a function of $\Phi_{\text{ph}}$ in Figs. 2(c) and 2(d), respectively. For MoSe₂/SiO₂ and decoupled Gr/MoSe₂, $I_{\text{PL}}^{A,B}/\Phi_{\text{ph}}$ drops abruptly as $\Phi_{\text{ph}}$ is increased. This effect stems from highly efficient exciton-exciton annihilation (EEA), as previously evidenced in TMD monolayers [65,66]. In the case of coupled Gr/MoSe₂, $I_{\text{PL}}^{A,B}/\Phi_{\text{ph}}$ remains constant, within experimental accuracy, up to $\Phi_{\text{ph}} \approx 10^{24} \text{ cm}^{-2} \text{ s}^{-1}$. As a result, while $I_{\text{PL}}^{A}$ is about 300 times weaker on coupled Gr/MoSe₂ than on bare MoSe₂ at $\Phi_{\text{ph}} = 3 \times 10^{20} \text{ cm}^{-2} \text{ s}^{-1}$, this quenching factor reduces down to about 3 at $\Phi_{\text{ph}} = 6 \times 10^{23} \text{ cm}^{-2} \text{ s}^{-1}$. Strong PL quenching, together with the linear scaling of $I_{\text{PL}}^{A,B}$ with $\Phi_{\text{ph}}$, demonstrates that interlayer coupling between graphene and MoSe₂ opens up a nonradiative decay channel for A excitons, which dramatically reduces the A-exciton lifetime and is sufficiently fast to bypass EEA. Very similar PL quenching and exciton dynamics have been observed in other Gr/MoSe₂/SiO₂ samples (see Ref. [52], Figs. S11–S13) as well as in Gr/WSe₂/SiO₂ (see Ref. [52], Fig. S14) and Gr/WSe₂/SiO₂ (data not shown). The shortening of the A-exciton lifetime is further substantiated by the analysis of the hot luminescence from the B exciton (note that our samples are photoexcited at 2.33 eV, i.e., well above the B exciton in MoSe₂). In bare MoSe₂ and decoupled Gr/MoSe₂, $I_{\text{PL}}^{A,B} \approx I_{\text{PL}}^{A}$, whereas $I_{\text{PL}}^{A,B} \approx I_{\text{PL}}^{A}$ in coupled Gr/MoSe₂. Interestingly, $I_{\text{PL}}^{A}$ is very similar in the three cases and scales linearly with $\Phi_{\text{ph}}$ [see Fig. 2(d)]. These observations suggest (i) that interlayer coupling does not significantly affect exciton formation and exciton decay until a population of A excitons is formed, and (ii) that the A-exciton lifetime in Gr/MoSe₂ is not appreciably longer than the B $\rightarrow$ A decay time. The latter is typically in the subpicosecond range [67] in atomically thin TMDs and provides a lower bound for the A-exciton lifetime in Gr/MoSe₂. Additional insights are provided by time-resolved photoluminescence measurements recorded in ambient conditions [see Fig. 2(e)]. Bare MoSe₂ and decoupled Gr/MoSe₂ display nonmonoeponential decays [68] with average exciton lifetime of about 1 ns. As anticipated, the PL decay of Gr/MoSe₂ is too fast to be resolved using our experimental apparatus, confirming that the A-exciton lifetime is significantly shorter than our time resolution of approximately 20 ps. Using the estimated decay time of bare MoSe₂ and a typical quenching factor of 300 (i.e., a quenching efficiency of 99.7%) in the low fluence limit, we can assume a conservative upper bound of a few ps for the exciton lifetime in coupled Gr/MoSe₂.

IV. INTERLAYER CHARGE TRANSFER

A. Net photoinduced electron transfer to graphene

The fast MoSe₂ exciton decay in Gr/MoSe₂ heterostructures may arise from a combination of ICT and IET processes. In this section, we introduce an original Raman-based readout of the steady-state charge carrier density in both materials.

Figure 3 shows the evolution of $\omega_G$, $\Gamma_G$, and $I_{2D}/I_G$ measured in sample S₁ as a function of $\Phi_{\text{ph}}$ in ambient air. The corresponding spectra are shown in Ref. [52] (Fig. S2). First, for Gr/SiO₂ and decoupled Gr/MoSe₂, $\omega_G \approx 1583 \text{ cm}^{-1}$, $\Gamma_G \approx 16 \text{ cm}^{-1}$, $\omega_{2D} \approx 2674 \text{ cm}^{-1}$, and $I_{2D}/I_G \approx 6.5$ do not show any appreciable variation as $\Phi_{\text{ph}}$ augments. These values correspond to very weakly doped graphene ($|n_{\text{Gr}}| \sim 10^{11} \text{ cm}^{-2}$ or $|E_F^{\text{Gr}}| \lesssim 100 \text{ meV}$) [47,48,69]. In addition, the absence of measurable phonon softening at high $\Phi_{\text{ph}}$ indicates that the laser-induced temperature rise remains below about 100 K [70].

Second, for coupled Gr/MoSe₂, $\omega_G$ distinctly rises as $\Phi_{\text{ph}}$ is increased, whereas $\Gamma_G$ decreases [see Figs. 3(a)–3(e)]. Additionally, $I_{2D}/I_G$ [Fig. 3(d)] drops significantly. These spectroscopic features provide strong evidence for net photoinduced ICT from MoSe₂ to graphene [47,48]. We can now identify the sign of the net transferred charge flow using the correlation between $\omega_{2D}$ and $\omega_{G}$ in Fig. 3(e) as in Refs. [48,55]. As $\Phi_{\text{ph}}$ is increased, the data for Gr/SiO₂ and decoupled Gr/MoSe₂ show no clear correlations. In contrast, on coupled Gr/MoSe₂, $\omega_{2D}$ and $\omega_{G}$ display a linear correlation with a slope of approximately 0.11, a value that clearly points towards photoinduced electron doping in graphene [48].

Using well-established theoretical modeling of electron-phonon coupling in doped graphene [46,71], we quantitatively determine the Fermi energy of graphene relative to the Dirac point $E_F^{\text{Gr}}$ or, equivalently, its doping level $n_{\text{Gr}}$. The values of $E_F^{\text{Gr}}$ and $n_{\text{Gr}}$ extracted from a global fitting procedure (see Ref. [48]) are plotted in Fig. 3(f).

As further discussed in Sec. V, $E_F^{\text{Gr}}$ ($n_{\text{Gr}}$) saturates as $\Phi_{\text{ph}}$ is increased and reaches up to approximately 280 meV ($\approx 5 \times 10^{12} \text{ cm}^{-2}$).
MoSe emission in our PL spectra. However, as in Sec. IVA, stable enough [72] to allow the observation of trion narrower (by approximately 20%) for coupled Gr Raman-active one-phonon modes in monolayer MoSe finite-momentum phonons, one can identify the two addition to several higher-order resonant features involving accumulation in MoSe [see Fig. 4(b)].

As in the case of graphene, changes in the Raman spectra can tentatively be assigned to doping, with possible spurious contributions from native strain, laser-induced heating, van der Waals coupling [75] and surface effects [76–78]. Interestingly, recent Raman studies in MoS2 monolayers have demonstrated that the $A'_{1}$-mode phonon undergoes modest doping-induced phonon renormalization, namely, a downshift and a broadening for increasing electron concentration, whereas the $E'$-mode phonon is largely insensitive to doping [50,51]. Conversely, also in MoS2, it was shown that under tensile (resp. compressive) strain, the $E'$-mode feature undergoes much larger shifts than the $A'_{1}$-mode feature [74,79]. The $A'_{1}$ and $E'$ phonons may thus be used as probes of ICT and strain, respectively. Based on these considerations, the minute $E'$ phonon softening observed irrespective of $\Phi_{ph}$ in Gr/MoSe2 relative to MoSe2/SiO2 suggests a slightly larger native tensile strain on Gr/MoSe2, which has no impact whatsoever on ICT (see Ref. [52], Fig. S4–S8). More importantly, the upshifted and narrower $A'_{1}$-mode feature consistently observed up to $\Phi_{ph} \approx 6 \times 10^{23}$ cm$^{-2}$ s$^{-1}$ in coupled Gr/MoSe2 indicates a lower electron density in MoSe2 than in decoupled Gr/MoSe2 and MoSe2/SiO2.

B. Hole accumulation in MoSe2

Net electron transfer to graphene naturally implies hole accumulation in MoSe2. Depending on the initial doping of MoSe2, photoinduced hole accumulation in MoSe2 should allow or impede the formation of charged excitons (trions). However, at room temperature, trions in MoSe2 are not stable enough [72] to allow the observation of trion emission in our PL spectra. However, as in Sec. IVA, we can seek for fingerprints of ICT in the high-resolution Raman response of MoSe2.

Figure 4(a) shows the MoSe2 Raman spectra from MoSe2/SiO2, and decoupled and coupled Gr/MoSe2. In addition to several higher-order resonant features involving finite-momentum phonons, one can identify the two Raman-active one-phonon modes in monolayer MoSe2 with $A'_{1}$ symmetry (near 242 cm$^{-1}$) and $E'$ symmetry (near 289 cm$^{-1}$) [73,74]. The faint $E'$ mode feature is slightly downshifted on coupled Gr/MoSe2, as compared to MoSe2/SiO2. The prominent $A'_{1}$-mode feature is similar for MoSe2/SiO2 and decoupled Gr/MoSe2, but it distinctively blueshifts (by approximately 0.5 cm$^{-1}$) and gets narrower (by approximately 20%) for coupled Gr/MoSe2 [see Fig. 4(b)].
These observations correspond to a net photoinduced hole temperature increase (estimated below 100 K [80]) at $\Phi_{ph}$ decoupled Gr (resp. FWHM) of the MoSe$_2$ doping in MoSe$_2$, namely, the $A'_1$ and $E'$ modes. The corresponding atomic displacements are sketched. (b) Extracted frequency (top) and FWHM (bottom) of the $A'_1$-mode feature as a function of the incident photon flux $\Phi_{ph}$ for MoSe$_2$/SiO$_2$ (green diamonds), coupled (red squares) and decoupled (blue circles) Gr/MoSe$_2$. The solid lines are linear fits. (c) Difference between the $A'_1$-mode frequencies $\Delta \omega_{A'_1}$ for coupled and decoupled Gr/MoSe$_2$ (open circles), and for coupled Gr/MoSe$_2$ and MoSe$_2$/SiO$_2$ (filled diamonds). All measurements were performed in ambient air.

However, in the three regions of the sample, the frequency (resp. FWHM) of the $A'_1$-mode feature downshifts (resp. upshifts) linearly as $\Phi_{ph}$ is increased, respectively. Such trends counterintuitively suggest photoinduced electron doping in MoSe$_2$. We tentatively assign the observed evolution of the $A'_1$-mode feature to a slight laser-induced temperature increase (estimated below 100 K [80] at $\Phi_{ph} \approx 6 \times 10^{23}$ cm$^{-2}$ s$^{-1}$), possibly combined with related photogating effects involving the presence of molecular adsorbates and trapped charges both acting as electron acceptors and laser-assisted desorption of the latter [51]. Remarkably, as shown in Fig. 4(c), the difference between the $A'_1$ frequencies (FWHM) measured on coupled Gr/MoSe$_2$ and decoupled Gr/MoSe$_2$ or MoSe$_2$/SiO$_2$ monotonically increases (decreases) as $\Phi_{ph}$ is increased. These observations correspond to a net photoinduced hole doping for MoSe$_2$ in coupled Gr/MoSe$_2$, relative to decoupled Gr/MoSe$_2$ and MoSe$_2$/SiO$_2$, consistently with the net photoinduced electron transfer from MoSe$_2$ to graphene demonstrated in Fig. 3.

V. ENVIRONMENTAL EFFECTS

The charge density and exciton dynamics in 2D materials are known to be influenced by environmental effects, in particular, by molecular adsorbates and the underlying substrate [49,51,81,82]. To determine the generality of the results presented above, we compare, in Figs. 5(a) and 5(b), the evolution of $E_F^{Gr}$ with increasing $\Phi_{ph}$ recorded in ambient air and under high vacuum ($\lesssim 10^{-4}$ mbar) for a set of five samples, wherein strong PL quenching has been observed (see Ref. [52], Fig. S11). Remarkably, in ambient air, all samples display (i) different initial doping at low $\Phi_{ph}$, (ii) distinct sublinear rises of $E_F^{Gr}$ with increasing $\Phi_{ph}$, and (iii) similar saturation at $E_F^{Gr}$ around 290 ± 15 meV [i.e., $n_{Gr} \approx (5 \pm 0.5) \times 10^{12}$ cm$^{-2}$]. Interestingly, under
These adsorbates are efficient electron traps [49, 51, 81], are removed, including through laser-assisted desorption. In ambient conditions and in vacuum, we systematically observe a transient regime with a photoinduced rise of $\Phi_{ph}$; e eF i g. 5(b) and Ref. [52], Fig. S11) a MoSe$_2$/Gr/SiO$_2$ vdWH. Remarkably, the results obtained on this inverted heterostructure are very similar to those obtained on Gr/MoSe$_2$/SiO$_2$ vdWHs.

Finally, we have compared the PL in Gr/MoSe$_2$/SiO$_2$ and MoSe$_2$/Gr/SiO$_2$ in ambient air and under vacuum conditions. While the PL of bare MoSe$_2$ is—as previously reported [81]—quenched under vacuum, the PL intensity and line shape measured as a function of $\Phi_{ph}$ in ambient air and under vacuum in Gr/MoSe$_2$ are not appreciably different (see Fig. 6 and Ref. [52], Fig. S12).

VI. DISCUSSION

The complementary results reported in Secs. III–V now make it possible to address a set of open questions of high relevance for fundamental photophysics and optoelectronic applications. What are the microscopic mechanisms responsible for net electron transfer and its saturation (Sec. VI A)? What is the impact of excitonic effects on interlayer coupling (Sec. VI B)? What are the relative contributions of ICT and IET to the massive photoluminescence quenching analyzed in Fig. 2 (Sec. VI C)?

A. Charge transfer mechanism

The clear saturation of the net photoinduced ICT in Gr/TMD heterostructures shown in Fig. 5 has not been reported thus far, and we first discuss the underlying microscopic ICT mechanisms. Since the Dirac point of graphene is located between the valence band maximum and the conduction band minimum of MoSe$_2$ [83–85], the tunneling of photoexcited electrons and holes to graphene can be envisioned as long as energy and momentum are conserved and $E_F^{Gr}$ lies sufficiently below (above) the conduction band minimum (valence band maximum) of MoSe$_2$. Electron transfer and hole transfer to graphene are sketched in Figs. 7(a) and 7(b). To account for our experimental findings, we propose the following scenario.

The band structure of coupled Gr/MoSe$_2$ can be, in a first approximation, considered as the superposition of the bands of the different materials [23, 86] separated by a subnanometer “van der Waals gap.” The relative position of the band structure is determined by the offsets between the Dirac point of graphene and the valence (conduction) band maximum (minimum) of MoSe$_2$. In the dark, without loss of generality, we may assume that both graphene and MoSe$_2$ are quasineutral. When visible light is shined onto Gr/MoSe$_2$, electron-hole pairs and excitons are mainly created in MoSe$_2$ since the latter absorbs significantly more
than graphene [27,54]. At this point, given the very close electron and hole effective masses in MoSe$_2$ [87], the rates of photoinduced electron and hole transfer from MoSe$_2$ to graphene will chiefly depend on the wave-function overlap, the density of states in graphene, and the energy difference between the band extrema in MoSe$_2$ and $E_F^{\text{Gr}}$.

Assuming the Dirac point lies closer to the valence band maximum than to the conduction band minimum [83,84], the photoinduced electron current to graphene should exceed the hole current immediately after sample illumination, consistently with our experimental findings. Because of the small density of states of graphene near its Dirac point [12], the net electron transfer to graphene induces a sizable rise of $E_F^{\text{Gr}}$ above the Dirac point. Thus, as $E_F^{\text{Gr}}$ moves away from the valence band maximum in MoSe$_2$, the hole current to $n$-doped graphene increases significantly. The vanishing of the net electron transfer to graphene then results from the cancellation of the photoinduced electron [Fig. 7(a)] and hole [Fig. 7(b)] currents. In vacuum and in the absence of adsorbates, this saturation is reached in the steady state at any $\Phi_{\text{ph}}$. In ambient air, electrons may escape from graphene (in Gr/MoSe$_2$/SiO$_2$) or MoSe$_2$ (in MoSe$_2$/Gr/SiO$_2$), resulting (at intermediate $\Phi_{\text{ph}} < 10^{23}$ cm$^{-2}$ s$^{-1}$) in a steady-state $E_F^{\text{Gr}}$ below the $\Phi_{\text{ph}}$-independent saturation value observed in vacuum [see Fig. 5(b)] [88].

The very similar saturation values of $E_F^{\text{Gr}}$ uncovered in several Gr/MoSe$_2$ samples both in ambient air and in vacuum (see Fig. 5) suggest a limit set by the intrinsic band offsets between graphene and MoSe$_2$, as well as the electron and hole tunneling efficiencies. The latter are affected by extrinsic materials properties, such as the presence of band-tail states as well as other traps and defects [89]. Systematic studies using other TMDs with distinct band offsets relative to graphene and controlled amounts of impurities and/or defects will help determine the extrinsic and intrinsic effects in the net charge transfer saturation. Nevertheless, our work is a step towards the optical determination of band offsets in van der Waals heterostructures. Confronted with electron transport measurements [90], or angle-resolved photoemission spectroscopy [23,85], our Raman-based approach may unveil the impact of strong band-gap renormalization and exciton binding energy on the optoelectronic properties of TMDs and related vdWHs.

**B. Impact of excitonic effects**

Indeed, although PL measurements (see Fig. 2) make it clear that excitons are formed in MoSe$_2$, the impact of excitonic effects on interlayer coupling and, more generally, on the optoelectronic response of vdWH remains elusive.

Upon optical excitation well beyond the optical band gap (as is the case in Figs. 1–6), free electron-hole pairs and tightly bound excitons can be formed in Gr/MoSe$_2$ [60,62]. Despite exciton formation being highly efficient and occurring on subpicosecond to a few picosecond time scales [68,91], our PL measurements have revealed equally short band-edge (A) exciton lifetimes in Gr/MoSe$_2$ (see Fig 2). Therefore, the observed interlayer coupling processes may certainly involve band-edge excitons but may also imply direct hot carrier and/or higher-order exciton transfer to graphene. To assess the contribution of out-of-equilibrium effects, we have combined PL and Raman measurements in ambient air and in vacuum on a Gr/WS$_2$/SiO$_2$ vdWH at two different laser photon energies near the $B$ exciton (2.33 eV) and slightly below the $A$ exciton (1.96 eV). In the latter case, only $A$ excitons can be formed by means of an upconversion process [92,93] (see Ref. [52], Fig. S14). For both including photon energies, we observe strong PL quenching, as well as photoinduced doping, very similar to the observations discussed in Figs. 2–6 for Gr/MoSe$_2$ vdWHs. These observations indicate that ICT and IET processes in GR/TMD vdWH mainly involve band-edge TMD excitons [94]. This result illustrates the unusually strong excitonic effects in TMDs, which must be taken into consideration when adapting free-carrier optoelectronic models to the case of vdWH-based devices.

**FIG. 6.** Comparison between the dependence of the Fermi energy in graphene $E_F^{\text{Gr}}$ (left axis, red) and the PL intensity of the A exciton in MoSe$_2$ $I_{A \text{Pl}}$ (right axis, blue) on $\Phi_{\text{ph}}$, measured on sample S$_2$ (a) in ambient air and (b) in vacuum at a laser photon energy of 2.33 eV. The dashed lines are linear fits to the photoluminescence data.
C. Charge vs energy transfer

Finally, we address the competition between ICT and IET. Let us first recall that Raman measurements probe the steady-state charge carrier densities in our samples and do not make it possible to extract electron and hole transfer rates. Figure 6 summarizes our findings by confronting the dependence of $E_{Gr}$ and $I_{PL}$ on $\Phi_{ph}$ in sample $S_2$. The key implications of our combined PL and Raman study are that the short exciton lifetime in Gr = MoSe$_2$ is (i) independent of $\Phi_{ph}$ (over nearly 4 orders of magnitude), (ii) unaffected by the environmental conditions (air vs vacuum), and, crucially, (iii) unaffected by the presence (in air, at low $\Phi_{ph}$) or absence (in vacuum at any $\Phi_{ph}$, or in air at high $\Phi_{ph}$) of net photoinduced ICT (here, electron transfer from MoSe$_2$ to graphene; see also Ref. [52], Fig. S13).

Our data demonstrate that, although electrons and holes may transfer to graphene, ICT processes alone (even in the case of balanced electron and hole transfer) cannot be responsible for the massive PL quenching and linear rise of the PL intensity vs $\Phi_{ph}$. Instead, IET—either in the form of electron exchange [i.e., Dexter-type IET, Fig. 7(c)] or dipole-dipole interaction [i.e., Förster-type IET, Fig. 7(d)]—provides a highly efficient relaxation pathway for excitons in Gr/TMD heterostructures.

Consequently, the exciton lifetime of about 1 ps deduced from PL measurements (see Sec. III) can be considered as a fair estimation of the energy-transfer time scale from a TMD monolayer to a graphene monolayer placed in its immediate vicinity. Since interlayer coupling is highly sensitive to minute changes (at the Å level) in the distance between 2D layers as well as to the distribution of TMD excitons in energy-momentum space [42,68], a timely theoretical and experimental challenge is to unravel the distance and temperature dependence of the energy-transfer rate and quantify contributions stemming from short-range (Dexter) and longer-range (Förster) mechanisms.

Let us add the following comments in order to tentatively pinpoint the microscopic energy-transfer mechanism. First, although balanced ICT and Dexter-type IET follow a priori two distinct microscopic mechanisms [see Figs. 7(a)–7(c)], both processes imply charge tunneling (i.e., wave-function overlap) and result in a similar final state where the energy of an exciton population is transferred to graphene. Interestingly, it was recently predicted in porphyrin/graphene hybrids that Dexter ET is largely inefficient compared to Förster ET even at subnanometer distances [95]. In the case of Gr/TMD vdWHs, the large in-plane dipoles in monolayer TMDs [96] should further favor Förster energy transfer to graphene. Along this line, the exciton lifetime measured in decoupled Gr/MoSe$_2$/SiO$_2$ [see Fig. 2(e)] is of the same order of magnitude yet appreciably shorter than in MoSe$_2$/SiO$_2$, an effect that may tentatively be assigned to long-range Förster energy transfer [97].

VII. CONCLUSION AND OUTLOOK

We have exploited complementary insights from micro-Raman and photoluminescence spectroscopies to disentangle contributions from interlayer charge and energy transfer in graphene/TMD heterostructures and establish the key role of energy transfer. These general findings advance our fundamental understanding of light-matter interactions at atomically thin heterointerfaces and have far-reaching consequences for applications.

Indeed, the graphene/TMD system is a ubiquitous building block in emerging optoelectronic nanodevices. Having established that band-edge TMD excitons transfer to graphene with near-unity efficiency, a key challenge is...
now to separate the electron-hole pairs formed in graphene [98] and enhance photoconductivity and/or photocurrent generation before these charge carriers release their energy into heat on a subpicosecond time scale [99,100].

The competition between interlayer charge and energy transfer is also a matter of active debate in related systems, e.g., in TMD/TMD type-II heterojunctions [32–37], which are also of high relevance for optoelectronics [10] and valleytronics [31]. We have shown that fingerprints of interlayer charge transfer are encoded in the Raman response of TMD monolayers. Combining Raman measurements and photoluminescence spectroscopy of interlayer excitons should provide a more comprehensive picture of exciton dynamics in these atomically thin semiconductor heterostructures.

More broadly, van der Waals heterostructures are also an emerging platform to explore many-body effects and new regimes of strong and/or chiral light–matter interactions. Further developments in these areas will benefit from the present insights into interlayer charge and energy transfer.

ACKNOWLEDGMENTS

We thank D. M. Basko, C. Robert, D. Lagarde, X. Marie, A. Ouerghi, G. Schull, and C. Genet for fruitful discussions. We are grateful to J. Chrétien for his early contribution to experimental measurements, to H. Majjad and M. Rastei for help with AFM measurements, and to the StNano clean room staff and M. Romeo for technical assistance. We acknowledge financial support from the Agence Nationale de la Recherche (under Grant No. H2DH ANR-15-CE24-0016) and from the LabEx NIE (under Grant No. ANR-11-LABX-0058-NIE within the Investissement d’Avenir program ANR-10-IDEX-0002-02). APPENDIX: EXPERIMENTAL DETAILS

Gr/MoSe$_2$ vdWHS were prepared on Si wafers covered with a 90-nm-thick SiO$_2$ epilayer using a viscoelastic transfer technique [101]. The Gr/MoSe$_2$ vdWHS were first characterized by AFM and then by micro-PL and micro-Raman measurements. As-prepared samples [such as sample S$_1$ discussed above; see Fig. 1(a)] as well as annealed samples (1 hour at 150°C and 2 hours at 200°C in high vacuum) such as sample S$_3$ were studied. Although more contamination “pockets” (see Ref. [52], Fig. S1) are present on as-prepared samples, we could observe, both in annealed and as-prepared samples, extended (>25 $\mu$m$^2$) coupled Gr/MoSe$_2$ domains with smooth and uniform interfaces due to a self-cleaning process [11].

PL and Raman studies were carried out in ambient air and in high vacuum, in a backscattering geometry, using a home-built confocal microscope. Unless otherwise noted, the samples were optically excited using a single longitudinal-mode, linearly polarized, 2.33-eV (532-nm) continuous-wave laser. The collected light was dispersed onto a charged-coupled-device array by a single (500 nm in focal length) monochromator equipped with a 150 (resp. 900 for graphene, 2400 for MoSe$_2$) grooves/mm grating for PL (resp. Raman) measurements. Spectral resolutions of 1.4 cm$^{-1}$ and 0.6 cm$^{-1}$ were obtained for Raman measurements with the 900 and 2400 grooves/mm grating, respectively. The sample holder was mounted onto a x-y-z piezoelectric stage, allowing hyperspectral imaging. Time-resolved PL measurements were performed on the same setup using a pulsed supercontinuum laser, with a repetition rate tunable from 1.95 MHz up to 78 MHz. The unpolarized output of the supercontinuum laser at 1.96 eV (633 nm) was selected using an acousto-optic tunable filter. PL decays were obtained using an avalanche photodiode coupled to a time-tagger, time-correlated, single-photon counting board. We have employed a very broad range of incident photon fluxes, resulting in exciton densities below and beyond the values achieved in earlier works [18,20,59]. The incident photon flux $\Phi_{ph}$ was obtained by measuring the laser power and the area of the laser spot. For instance, with a measured optical power of 1 $\mu$W at the objective at 2.33 eV, we obtained a photon flux of $2.2 \times 10^{21}$ cm$^{-2}$ s$^{-1}$ using a 100x objective with a numerical aperture of 0.9. The Raman peaks were fit using Lorentzian and modified Lorentzian [48,56] profiles for the G- and 2D-mode features, respectively, and Voigt profiles (with a fixed Gaussian width taking into account our spectral resolution) for MoSe$_2$ features. Therefore, in Fig. 4(b), the linewidth $\Gamma_{ai}^0$ has to be understood as the Lorentzian FWHM extracted from a Voigt fit.

[78] The observed upshift may, in part, stem from van der Waals coupling between the graphene and MoSe$_2$ monolayers [74–77] (similarly to the case of TMD bilayers), as well as from surface effects [76,77], i.e., in the present case, slightly larger force constants between Mo and Se atoms in Gr/MoSe$_2$/SiO$_2$ than in air/MoSe$_2$/SiO$_2$. However, neither kind of effect would lead to the significant narrowing of the $A'_1$ feature observed in Gr/MoSe$_2$/SiO$_2$, and they cannot account for the differential effects shown in Fig. 4(c).

[88] As a result, the relative magnitudes of the electron and hole flows, and the resulting steady-state $E^n$ are not exclusively determined by $\Phi_{ph}$ (compare data in Fig. 5 and see Ref. [52], Fig. S13).

[94] This conclusion is consistent with the fact that momentum conservation can be more easily fulfilled for an exciton than for a free charge carrier. Indeed, an exciton in the TMD can decay by transferring an electron or hole to a finite-momentum state graphene, leaving the other carrier in the TMD with the excess momentum [see Figs. 7(a) and 7(b)], whereas at room temperature, a free charge carrier near the band edges would need extra momentum provided by defect or phonon scattering.

[97] Let us note that the PL data in Figs. 1(f) and 2(e) have been recorded on a freshly made sample S1 before recording the data in Figs. 2(c) and 2(d). Aging of the air-exposed MoSe2 layer in S1 is likely responsible for the fact that in Figs. 2(c) and 2(d), the PL intensity in MoSe2/SiO2 is slightly smaller than in decoupled Gr/MoSe2/SiO2, where graphene acts as an efficient passivating layer.

Correction: The previously published Figures 2(c) and 2(d) contained axis label errors and were replaced.
